Dispersion relations

□ If there are f_j electrons per molecule that are in this situation, with damping constant γ_j and natural frequency ω_j , then the contribution of the *j*th kind of bond to the dipole moment per unit volume, P_j , is

$$P_j = N f_j p_j = \frac{Nq^2}{m_e} \frac{f_j E_{0j} e^{-i\omega t}}{\left(\omega_j^2 - \omega^2\right) - i\gamma_j \omega}$$

where E_{0j} is the component of E in the bond direction. The net dipole moment per unit volume from *all* of the bonds is the vector sum

$$\boldsymbol{P} = \frac{Nq^2}{m_e} \sum_{j=1}^{M} \frac{f_j}{\left(\omega_j^2 - \omega^2\right) - i\gamma_j \omega} \boldsymbol{E}(t) \quad .$$

Far from any resonances, the index of refraction rises gently as frequency increases. This is what one might call **ordinary dispersion**. Most common glasses exhibit ordinary dispersion at visible wavelengths.

- □ This increase, however, turns out to be due to those distant resonances.
- □ As frequency passes through a resonance, the index decreases sharply, then resumes its gentle increase. The sudden decrease is called **anomalous dispersion**.
- □ The absorption coefficient is small far from resonance, but peaks sharply on resonance. (See example on next page.)
