# Simulation and Random Number Generation in Physics

“Monte Carlo” methods are a broad set of techniques for calculating probabilities and related quantities using sequences of random numbers.

- ▶ Simulate physical systems with models of noise and uncertainty
- ▶ Simulate data with known inputs to stress-test your analysis (“data challenges”). Can be quite extensive...
- ▶ Perform calculations that cannot be done analytically or with a deterministic algorithm. E.g., function minimization, or many high-dimensional integrals
- ▶ **Inverse Monte Carlo**: estimate best-fit parameters with uncertainties using many simulated data sets – avoid explicit and difficult uncertainty propagation

All this depends upon the generation of (pseudo-)random numbers. This means **you MUST understand how random number generators (RNGs) work!**

# Example Simulation from U of R Faculty

Physics of granular materials which become rigid with increasing density (“jamming” transition) [1]:

## Universality of Jamming Criticality in Overdamped Shear-Driven Frictionless Disks

Daniel Vågberg,<sup>1</sup> Peter Olsson,<sup>1</sup> and S. Teitel<sup>2</sup>

<sup>1</sup>Department of Physics, Umeå University, 901 87 Umeå, Sweden

<sup>2</sup>Department of Physics and Astronomy, University of Rochester, Rochester, New York 14627, USA

(Received 18 December 2013; revised manuscript received 4 August 2014; published 3 October 2014)

We investigate the criticality of the jamming transition for overdamped shear-driven frictionless disks in two dimensions for two different models of energy dissipation: (i) Durian’s bubble model with dissipation proportional to the velocity difference of particles in contact, and (ii) Durian’s “mean-field” approximation to (i), with dissipation due to the velocity difference between the particle and the average uniform shear flow velocity. By considering the finite-size behavior of pressure, the pressure analog of viscosity, and the macroscopic friction  $\sigma/p$ , we argue that these two models share the same critical behavior.

## Example “Data Challenge”

The Laser Interferometer Gravitational Wave Observatory (LIGO) is (in)famous for carrying out extensive data challenges [2]

Very important to conduct end-to-end “stress tests” in background-dominated analyses. Above: fake binary merger injected into LIGO data stream, 2011

# Example of Inverse Monte Carlo

# Pseudo-Random Numbers

- ▶ We need to generate sequences of random numbers to model noise and uncertainty.

- ▶ Computers are not random, they are deterministic. So how do we get random sequences of numbers?
- ▶ Answer: **we don't**. We get *pseudo*-random sequences and try to use them in clever ways.

# Pseudo-Random Number Generators (RNGs)

## Linear Congruential Generator

- ▶ An old but popular technique of generating pseudo-random number sequences is the **linear congruential generator** (LCG)
- ▶ A sequence of values  $x_i$  is generated using the recurrence relation

$$x_{n+1} = (ax_n + c) \bmod m$$

- ▶ Generate integers in  $[0, m - 1]$ . The longest sequence with no repeating values, called the **period** of the RNG, is at most  $m$ .
- ▶ Note: if  $m$  is an unsigned integer (`uint32_t` on most systems) then the period will be  $2^{32} \approx 4 \times 10^9$ . ( $2^{64} \approx 10^{18}$ .) Most real simulations need orders of magnitude more numbers than this!
- ▶ **Hull-Dobell Theorem**: the full period is achieved iff  $c$  and  $m$  are co-prime,  $a - 1$  is divisible by all prime factors of  $m$ , and  $a - 1$  is a multiple of 4 if  $m$  is a multiple of 4.

# Choosing the Random Seed

- ▶ Note that the LCG is deterministic. If you start from the **same**  $x_0$ , a value known as the **seed**, you always get the **same sequence**.
- ▶ The choice of seed can affect the performance of the LCG; i.e., a poor choice could lead to a period  $\ll m$ .
- ▶ Determinism is great for debugging, but if you generate the same numbers over and over you aren't getting a pseudo-random sequence
- ▶ **Common mistake**: accidentally hardcoding the seed into your simulation code
- ▶ **Solution 1**: use system clock to choose  $x_0$  via a call to `time(0)`; returns time in seconds since 00:00 UT, 1 Jan 1970 (Unix epoch).
  - ▶ Be careful to use the lowest-order bits of the time, including milliseconds. If you just use the seconds, what happens on a computing cluster if multiple jobs start simultaneously?

Good enough for physics simulations, but not cryptography

# Choosing the Random Seed

- **Solution 2:** use the reservoir of random bits in computer's **entropy pool**, accessible in `/dev/random`. Could be noise measured in a resistor, or clock drift [4], or a peripheral device connected to a source of quantum randomness

- However you generate the seed, make sure you **always save the seed value** so you can regenerate the sequence later for checks!

# Known Issues to Watch For

- ▶ The LCG is fast but has some known problems
- ▶ Many RNGs can produce hidden **long-range correlations** between values in the sequence.
- ▶ **Ex.:** if you generate  $n$ -dimensional points with the LCG, the points will lie on  $(n!m)^{1/n}$  hyperplanes [5].
- ▶ Clearly random numbers shouldn't do that.
- ▶ Could this affect your simulation? Maybe. Depends on your application.

# Alternatives to the LCG

## Mersenne Twister

- ▶ Most popular RNG currently in use is an algorithm called the **Mersenne Twister** [6], which uses the matrix linear recurrence relation

$$x_{k+n} = x_{k+m} \oplus (x_k^u \mid x_{k+1}^l) \mathbf{A}$$

with  $\mid$  = bitwise OR and  $\oplus$  = bitwise XOR.

- ▶ For  $n$  = degree of recurrence,  $w$  = word size in bits, and  $0 \leq r \leq w - 1$  = bits in lower bitmask, the algorithm requires that the period length

$$2^{nw-r} - 1$$

is a **Mersenne prime** – a prime number of the form  $2^n - 1$ .

- ▶ The MT implementation in Python and C++ (Boost, ROOT) has period  $2^{19937} - 1 \approx 4 \times 10^{6001}$ .

# Alternatives to the LCG

## Xorshift Algorithms

- ▶ Another class of RNG is called Xorshift (“XOR-shift”), which depends on a combination of **XOR** and **bit shift** operations [7].
- ▶ These are extremely fast because XOR and shifting are simple CPU instructions. Example: a  $2^{128} - 1$  period algorithm

```
#include <stdint>

// State variables; start s.t. not all = 0
uint32_t x, y, z, w;

uint32_t xorshift128() {
    uint32_t t = x ^ (x << 11);
    x = y; y = z; z = w;
    return w = w ^ (w >> 19) ^ t ^ (t >> 8);
}
```

# Human-Generated Random Numbers

- ▶ How good are you at generating random numbers?

## Example

Without over-thinking this, take a minute to write down as many random values between 1 and 100 as you can.

- ▶ What does the distribution of numbers look like?
- ▶ How would you tell if this is really a random sequence? Is it easy to predict parts of the sequence (auto-correlation)?
- ▶ Do we need to specify more information to answer this question?

# Benford's Law

- ▶ If you are like most people, you didn't repeat numbers enough (remember the demon in the cartoon...)
- ▶ Also, your “random” sequence is probably uniform between 1 and 100
- ▶ However, in many sources of data the values follow a distribution known as **Benford's Law**: 1 is the leading digit 30% of the time, 2 is the leading digit 18% of the time, etc.
- ▶ If you pick a number randomly from the logarithmic number line, it will roughly follow Benford's Law

- ▶ This rule can be used to detect fraudulent numbers in elections, accounting (stock prices), and scientific papers.

# Generating Arbitrary Random Numbers

- ▶ All of the RNGs we have discussed will produce uniformly distributed random numbers:
  - ▶ LCG generates numbers between  $[0, m]$
  - ▶ MT generates numbers between  $[0, 1]$
- ▶ This is great for situations when you want a uniform distribution, but that does not correspond to most physical situations
- ▶ Luckily, there are several ways to convert a uniform distribution to an arbitrary distribution:
  1. Transformation or inversion method
  2. Acceptance/rejection method
- ▶ The transformation method is generally the most efficient technique, but it is only applicable in cases where the PDF you want is integrable and the CDF can be inverted
- ▶ Acceptance/rejection is less efficient but works for any PDF you will want to use for random draws

# Transformation/Inversion Method

Given a PDF  $p(x|I)$  and its CDF  $F(x) = \int_{-\infty}^x p(x'|I) dx'$ :

1. Generate a **uniform random number**  $u$  between  $[0, 1]$
2. Compute the value  $x$  s.t.  $F(x) = u$
3. Take  $x$  to be the random draw from  $p(x|I)$

In other words, from  $u$  and the invertible CDF  $F(x)$ , the value  $x = F^{-1}(u)$  is distributed according to  $p(x|I)$ .

# Transformation/Inversion Method

## Exponential Distribution

### Example

The PDF of the exponential distribution is

$$p(x|\xi) = \frac{1}{\xi} e^{-x/\xi}$$

and the CDF is

$$F(x) = P(X \leq x|\xi) = \int_0^x \frac{1}{\xi} e^{-x'/\xi} dx' = 1 - e^{-x/\xi}$$

Therefore, given  $u \in [0, 1]$  we can generate  $x$  according to  $p(x|\xi)$  by inverting the CDF:

$$u = F(x) = 1 - e^{-x/\xi}$$

$$x = F^{-1}(u) = -\xi \ln(1 - u) = -\xi \ln u$$

# Limits of the Inversion Method

- ▶ Inversion is very efficient and great if you can invert your CDF
- ▶ Unfortunately this condition is not fulfilled even for many basic 1D cases

## Example

The CDF of the Gaussian distribution is

$$F(x) = \int_{-\infty}^x p(x|\mu, \sigma) = \frac{1}{2} \left[ 1 + \operatorname{erf} \left( \frac{x - \mu}{\sigma\sqrt{2}} \right) \right]$$

The error function cannot be expressed in closed form, though there are numerical approximations to erf and erf<sup>-1</sup> in scipy.

- ▶ A trick for complicated PDFs: express the CDF as a tabulated list of values  $(u, F(x))$ , “invert” it, and **interpolate**.

# Acceptance/Rejection Method

Very old technique; modern form due to von Neumann. AKA “hit and miss,” it generates  $x$  from an arbitrary  $f(x)$  using a so-called **instrumental distribution**  $g(x)$ , where  $f(x) < Mg(x)$  and  $M > 1$  is a bound on  $f(x)/g(x)$ .

1. Sample  $x$  from  $g(x)$  and  $u \in [0, 1]$ .
2. Check if  $u < f(x)/Mg(x)$ 
  - ▶ Yes: accept  $x$
  - ▶ No: reject  $x$ , sample again

Very easy to implement, no limits on  $f(x)$ .

Calculation of  $\pi$ : uniformly generate  $(x, y)$  pairs in box, count up points inside the circle.  $\pi \approx 4N_{\text{circle}}/N_{\text{box}}$ .

# Buffon's Calculation of $\pi$

- ▶ An early variant of the Monte Carlo approach can be seen in Buffon's Needle (1700s), a method of calculating  $\pi$

Given a needle of length  $L$  dropped on a plane with parallel lines  $d$  units apart, what is the probability the needle will cross a line if  $L < d$ ?

- ▶  $x$  is center distance to nearest line;  $x \sim U(0, d/2)$
- ▶  $\theta$  is angle between needle center line:  $\theta \sim U(0, \pi/2)$
- ▶ Needle crosses line if  $x \leq L \sin \theta/2$ . Joint PDF:

$$P = \int_0^{\pi/2} d\theta \int_0^{L \sin \theta/2} dx \frac{4}{\pi d} = \frac{2L}{\pi d}$$

# Acceptance/Rejection Method

## Sampling from a 1D Distribution

### Example

Suppose  $f(x) = \frac{3}{8}(1 + x^2)$  for  $-1 \leq x \leq 1$ . (Aside: do you recognize this distribution?)

- ▶ Generate random  $x \in [-1, 1]$  and  $y \in [0, 0.75]$ .
- ▶ If  $y < f(x)$ , populate the histogram with  $x$ .

# Acceptance/Rejection Method

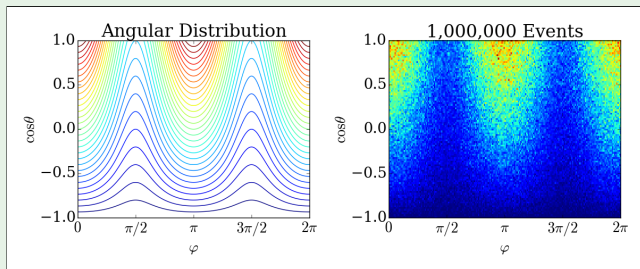

## Sampling from a 2D Distribution

### Example

Suppose we want to sample from the 2D angular distribution

$$\frac{1}{N} \frac{dN}{d \cos \theta d\varphi} = (1 + \cos \theta) \left(1 + \frac{1}{2} \cos 2\varphi\right)$$

Generate triplets  $(x, y, z)$ , where  $x = \varphi \in [0, 2\pi]$ ,  $y = \cos \theta \in [-1, 1]$ , and  $z \in [0, 3]$ , keeping  $(x, y)$  if  $z < f(x, y)$ :

# Limitations of Acceptance/Rejection

Ideally you know  $f_{\max}$  or normalize  $f(x) = p(x|I)$  to have a maximum of 1.

- ▶ If not, you'll have to pre-scan the parameter space in advance.

If  $f(x)$  ranges over many orders of magnitude, acceptance/rejection can be very inefficient as you'll waste lots of time in low-probability regions.

Possible approaches:

- ▶ Subdivide  $x$  into ranges with different  $f_{\max}$ .
- ▶ Use **importance sampling**, where you generate random numbers according to a function that envelopes the PDF you really want to sample

Example implementation: vegas package in Python, an implementation of the adaptive Monte Carlo VEGAS multi-dimensional integration algorithm [8]

# Monte Carlo Integration

- ▶ We can also solve integrals (esp. in several dimensions) with Monte Carlo. Mathematically, we approximate the integral by the average of the function of the interval of integration:

$$I = \int_a^b f(x) dx \approx (b-a) E(f(x))$$

- ▶ We take discrete samples of  $f$  and let the MC estimate converge to the true integral as the **number of samples gets large**:

$$E(f(x)) = \frac{1}{N} \sum_{i=1}^N f(u_i) \rightarrow \frac{1}{b-a} \int_a^b f(u) du$$

$$I = I_{MC} = \frac{b-a}{N} \sum_{i=1}^N f(x_i)$$

- ▶ Error on the result given by the Central Limit Theorem:

$$\sigma = \frac{\sqrt{V(f)}}{\sqrt{N}} \propto \frac{1}{\sqrt{N}}.$$

# Generating a Gaussian Random Number

How would you generate a Gaussian random number?

1. You can use inversion if you can numerically estimate  $\text{erf}^{-1}$ .
2. You can use the acceptance/rejection method if you don't mind wasting some calculations.
3. You can exploit the Central Limit Theorem. Sum 12 uniform variables, which approximates a Gaussian of mean  $12 \times 0.5 = 6$  and a variance of  $12 \times (1/12) = 1$ . Subtract 6 to get a mean of zero. This takes even more calculation and isn't exact.
4. Use the polar form of the binormal distribution

$$p(x, y|I) = \frac{1}{2\pi} \exp \left\{ -\frac{1}{2} (x^2 + y^2) \right\}$$

to generate two Gaussian random numbers at once.

# Box-Müller Algorithm

Re-express the 2D Gaussian PDF in polar coordinates:

$$\begin{aligned} p(x, y|I) \, dx \, dy &= \frac{1}{2\pi} \exp \left\{ -\frac{1}{2} (x^2 + y^2) \right\} \, dx \, dy \\ &= \frac{1}{2\pi} \exp -\frac{r^2}{2} r \, dr \, d\varphi \end{aligned}$$

Then generate an exponential variable  $z = r^2/2$ , change variables to  $r$ , and generate a uniform polar angle  $\varphi$ :

- ▶  $z = -\ln u_1$  for  $u_1 \sim U(0, 1)$
- ▶  $r = \sqrt{2z}$
- ▶  $\varphi = 2\pi u_2$  for  $u_2 \sim U(0, 1)$

Then  $x = r \cos \varphi$  and  $y = r \sin \varphi$  are two normally-distributed random numbers. Very elegant! But due to the calls to transcendental functions (sqrt, log, cos, etc.), numerical approaches could be faster in practice...

# Generating a Poisson Random Variable

The best way to generate a Poisson random variable is to use inverse transform sampling of the cumulative distribution.

- ▶ Generate  $u \sim U(0, 1)$
- ▶ Sum up the Poisson PDF  $p(n|\lambda)$  with increasing values of  $n$  until the cumulative sum exceeds  $u$ :

$$s_n = \sum_{k=0}^n \frac{\lambda^k e^{-\lambda}}{k!}, \quad \text{while } s_n < u$$

- ▶ Return the largest  $n$  for which  $s_n < u$ .

This will work quite well until  $\lambda$  gets large, at which point you may start experiencing **floating-point round-off errors** due to the factor of  $e^{-\lambda}$ . But for large  $\lambda$  you can start to use the Gaussian approximation.
